(Received 24 March 2003; accepted 15 April 2003)

We decompose the vertical electron detachment energies (VDEs) in solvated-electron clusters of alkali halides in terms of (i) an electrostatic contribution that correlates with the dipole moment (μ) of the individual alkali halide molecule and (ii) a relaxation component that is related to the polarizability (α) of the alkali halide molecule. Detailed numerical ab initio results for twelve species (MX)2n (M=Li,Na; X=F,Cl,Br; n = 2,3) are used to construct an interpolation model that relates the clusters’ VDEs to their μ and α values as well as a cluster size parameter r that we show is closely related to the alkali cation’s ionic radius. The interpolation formula is then tested by applying it to predict the VDEs of four systems [i.e., (KF)2, (KF)3, (KCl)2, and (KCl)3] that were not used in determining the parameters of the model. The average difference between the model’s predicted VDEs and the ab initio calculated electron binding energies is less than 4% (for the twelve species studied). It is concluded that one can easily estimate the VDE of a given high-symmetry solvated electron system by employing the model put forth here if the α, μ and cation ionic radii are known. Alternatively, if VDEs are measured for an alkali halide cluster and the α and μ values are known, one can estimate the r parameter, which, in turn, determines the “size” of the cluster anion. © 2003 American Institute of Physics. [DOI: 10.1063/1.1580113]

I. INTRODUCTION

It is known that a cluster of polar molecules is able to host an excess electron in at least two ways.1,2 The first possibility is that the electron can be tethered to the cluster via its interaction with the net dipole moment of the cluster. In such cases, the polar molecules tend to align head-to-tail to maximize their dipole moment and thus their binding energy. In such so-called “dipole-bound” anions, the extra electron is localized primarily outside the molecular framework on the positive side of the neutral parent, as demonstrated long ago by Jordan and Luken.3 Alternatively, an excess electron can be trapped inside the cluster, in which case at least two of the polar molecules align their dipole toward one another. The existence of the latter species, commonly referred to as solvated electron (SE) anions, has been known for more than 100 years when their bulk analogs were identified in solids and liquids.4,5 Since then, a very large number of the SE species have been investigated experimentally and theoretically.6–19 Among other differences between dipole-bound anions and solvated electrons, the latter species are known to possess relatively large vertical electron detachment energies and to undergo large geometrical rearrangements upon electron detachment because having dipoles directed toward one another is highly unfavorable in the absence of the electron.2,9,14,18

Large vertical electron detachment energies (VDEs) characterizing SE species have been reported in the literature recently. For example, the urea dimer “solvating” an excess electron has been found to possess a VDE of ~0.2, 0.5, and 0.9 eV, when two “canonical,” one canonical and one zwit-terionic, or two zwiterionic urea tautomers are involved, respectively.15 For a solvated electron trapped in a cluster consisting of two or three NaCl molecules, even larger VDEs have been found. In particular, the linear $D_{hh}$-symmetry sodium chloride negatively charged dimer cluster (in which two NaCl molecules are aligned in a head-to-head manner) binds an extra electron by 2.64 eV18 while the $D_{3h}$-symmetry (NaCl)$_3$ cluster has a VDE of 4.2 eV.19

The proposal that we intend to explore in the present work is that the large electron binding energies characterizing alkali halide SE systems can be correlated with two fundamental physicochemical properties (i.e., μ and α) of the monomers that constitute such clusters. To examine this hypothesis, we needed to undertake ab initio calculations of the VDE values for various SE species in order to generate the necessary VDE data. In so doing, we studied several previously unreported cluster anions, so our data represent new findings in these cases. To restrict the systems for which we

(Received 24 March 2003; accepted 15 April 2003)

We decompose the vertical electron detachment energies (VDEs) in solvated-electron clusters of alkali halides in terms of (i) an electrostatic contribution that correlates with the dipole moment (μ) of the individual alkali halide molecule and (ii) a relaxation component that is related to the polarizability (α) of the alkali halide molecule. Detailed numerical ab initio results for twelve species (MX)2n (M=Li,Na; X=F,Cl,Br; n = 2,3) are used to construct an interpolation model that relates the clusters’ VDEs to their μ and α values as well as a cluster size parameter r that we show is closely related to the alkali cation’s ionic radius. The interpolation formula is then tested by applying it to predict the VDEs of four systems [i.e., (KF)2, (KF)3, (KCl)2, and (KCl)3] that were not used in determining the parameters of the model. The average difference between the model’s predicted VDEs and the ab initio calculated electron binding energies is less than 4% (for the twelve species studied). It is concluded that one can easily estimate the VDE of a given high-symmetry solvated electron system by employing the model put forth here if the α, μ and cation ionic radii are known. Alternatively, if VDEs are measured for an alkali halide cluster and the α and μ values are known, one can estimate the r parameter, which, in turn, determines the “size” of the cluster anion. © 2003 American Institute of Physics. II. METHODS

The equilibrium geometries of the anionic species have been optimized at the second-order Møller–Plesset (MP2) level of theory. In these calculations, the values of \( \langle S^2 \rangle \) never exceeded 0.7526 for the doublet anionic states, so we are confident that spin contamination effects are not serious. The electronic binding energies (\( D \)) of the anions were calculated using second-order Møller–Plesset perturbation theory as well as the coupled-cluster method with single, double, and the conventional\(^{25} \) perturbative noniterative triple excitations (CCSD(T)).\(^{20} \) However, in the case of trimers containing bromine atoms \([\text{i.e., (LiBr)}_3^–\) and \((\text{NaBr})_3^–\)\] we had to limit our treatment to the CCSD level because even the perturbative inclusion triple excitations for these species was not feasible with the computer resources available. The choice of the atomic orbital basis set used to describe the neutral molecule and the excess bound electron is very important for reproducing the correct value of the electron binding energy. In this contribution we employed aug-cc-pVDZ basis sets\(^{21} \) whose usefulness for describing various molecular anions has been documented previously.\(^{22} \) The diffuse character of the orbital describing the “solvated” (excess) electron necessitates the use of extra diffuse basis functions having very low exponents and therefore our geometry optimization calculations were performed with the aug-cc-pVDZ+5s5p basis sets, while the electron binding energies were calculated with the aug-cc-pVDZ+6s6p4d basis sets. The additional 5s5p (or 6s6p4d) sets of diffuse functions were centered in the middle of the cluster \(\text{(i.e., in the symmetry center)}\) in each case, where the excess electron is localized \(\text{(see Fig. 1).}\) The extra diffuse functions do not share exponent values, and for calculating electron binding energies we used even-tempered\(^{23} \) six-term \(s\), six-term \(p\), and four-term \(d\) basis sets. The geometric progression ratio was equal to 3.2,\(^{24} \) and for each orbital symmetry, we started to build up the exponents of the extra diffuse functions from the lowest exponent of the same symmetry included in the aug-cc-pVDZ basis set for lithium or sodium. As a consequence, for lithium-containing species we used lowest exponents of \(0.04620731 \times 10^{-6}\), \(1.725554466 \times 10^{-6}\), and \(6.914138794 \times 10^{-4}\) a.u., for the \(s\), \(p\), and \(d\) symmetries, respectively, and for sodium-containing systems we employed lowest exponents of \(6.7520884 \times 10^{-6}\), \(5.8952718 \times 10^{-6}\), and \(4.4631956 \times 10^{-4}\) a.u., for the \(s\), \(p\), and \(d\) symmetries, respectively. We should note that, because the electron binding energies of the alkali halide clusters studied here are substantial \(\text{(at least 2 eV)}\), it is likely not necessary to use such a large set of diffuse basis functions. We employed these bases to make sure that our basis was adequate; our interest was not in determining the smallest basis that would be needed to obtain reasonable results.

A. Ab initio geometries and electron binding energies of the solvated electron species

In order to construct our model for interpolating \(\text{(and extrapolating)}\) the electronic stabilities of SE species, we selected several molecular clusters that form negative ions with the excess electron localized \text{inside} the cluster. Since the anions formed by alkali halide clusters had been the subject of an earlier extensive study of ours, we decided to use these species in our present study. Hence, we considered twelve clusters \(\text{(dimers and trimers): (NaF)}_2^+, \text{(NaF)}_3^+, \text{(NaCl)}_2^+, \text{(NaCl)}_3^+, \text{(NaBr)}_2^+, \text{(NaBr)}_3^+, \text{(LiF)}_2^+, \text{(LiF)}_3^+, \text{(LiCl)}_2^+, \text{(LiCl)}_3^+, \text{(LiBr)}_2^+, \text{and (LiBr)}_3^+.\) We first verified that all of these clusters have the ability to form SE species with the monomers directed inward and the extra electron localized inside the cluster. We recall that, to simplify the problem, only high-symmetry clusters were considered \(\text{(i.e., linear } D_{xh}\text{-symmetry structures in the case of the dimers and triangular } D_{3h}\text{-symmetry structures in the case of the trimers).}\) Noting this limitation is important because it is known that at least some such clusters also form alternative lower-symmetry structures, such as the \(X-M_e-M-X\) trimers \(\text{(where } e\text{ denotes the extra electron and } M\text{ and } X\text{ represent the alkali and halogen atom, respectively)}.\)\(^{14,19} \)
Due to the significant polarity of the monomers in each cluster (see Table I for monomers’ properties), we expected each of these species to form an electronically stable anion. The calculated \textit{ab initio} electron binding energies for the twelve clusters holding an extra electron confirmed this expectation (see Table II).

For each dimer anion, we found its local minimum (corresponding to the SE species) to possess \( D_{\alpha h} \) symmetry as depicted in Fig. 1. Similarly, for each trimer we obtained a local minimum at \( D_{1s} \) symmetry (see Fig. 1). The relevant geometric parameters describing these anions are collected in Table II where we show the intramonomer M–X distance (\( R \)) and the metal-to-cluster-center distance (\( r \)). While the former is the bond length of the monomer in the cluster, the latter may be interpreted as an approximate distance from the alkali atom M (representing the positively charge site of the monomer) to the site where the excess electron is localized. In addition, in Table II we give the self-consistent field (SCF) dipole moments [the SCF dipole moments of the neutral alkali halides are similar to those calculated from the MP2 electron densities and the largest difference (0.2 D) we found for NaF species] and polarizabilities of the neutral monomers.

Due to the significant polarity of the monomers in each cluster (see Table I for monomers’ properties), we expected each of these species to form an electronically stable anion. The calculated \textit{ab initio} electron binding energies for the twelve clusters holding an extra electron confirmed this expectation (see Table II).

For each dimer anion, we found its local minimum (corresponding to the SE species) to possess \( D_{\alpha h} \) symmetry as depicted in Fig. 1. Similarly, for each trimer we obtained a local minimum at \( D_{1s} \) symmetry (see Fig. 1). The relevant geometric parameters describing these anions are collected in Table II where we show the intramonomer M–X distance (\( R \)) and the metal-to-cluster-center distance (\( r \)). While the former is the bond length of the monomer in the cluster, the latter may be interpreted as an approximate distance from the alkali atom M (representing the positively charge site of the monomer) to the site where the excess electron is localized. In addition, in Table II we give the self-consistent field (SCF) dipole moments [the SCF dipole moments of the neutral alkali halides are similar to those calculated from the MP2 electron densities and the largest difference (0.2 D) we found for NaF species] and polarizabilities of the neutral monomers.

### Table I. The MP2 equilibrium bond lengths (\( R_{\alpha h} \)) and corresponding dipole moments calculated for the neutral monomers with the aug-cc-pVQZ + 6s6p4d basis sets. The CCSD(T) vertical electron binding energies (\( E_{\alpha h}^{\text{CCSD(T)}} \)) for the corresponding anions are also given (in eV). Bond lengths in Å, dipole moments in debyes, polarizabilities in bohr$^3$. The values of \( a \) correspond to the \( a_\mu \) terms of the polarizability tensor.

\(^\ast\) \(\Delta D_{\text{CCSD(T)}}\)

ride dimer and trimer as well as for the lithium fluoride dimer and trimer (forming SE structures). After analyzing the data in Table III it becomes clear that the \(\Delta D_{\text{HTSO}}\) terms are indeed not significant and responsible at most for 1% of the total electron binding energy (\(D\)). Therefore, we conclude that the inclusion of these terms is not necessary to estimate the electronic stabilities of the SE species with decent accuracy (although their consideration would be required if one wants to calculate very precise values of \(D\) for such systems).

The \textit{ab initio} results calculated for the twelve SE dimers and trimers used to construct our model indicate that, in fact, the electron binding energy is quite well reproduced even at the SCF level since the \(\Delta D_{\text{MP2}}\) term is always very small (see Table IV). This is due to the (partial) cancellation of the second-order dispersion and nondispersion terms as shown in Table IV (\(\Delta D_{\text{MP2}}\) can be partitioned into \(\Delta D_{\text{disp}}\) and \(\Delta D_{\text{nondisp}}\), see Ref. 9). It can be concluded that the \(\Delta D_{\text{MP2}}\) term does not exceed 0.05 eV in most cases and is usually smaller than 2% of \(D\). Therefore, we decided to focus on reproducing the \(\Delta D_{\text{SCF}}\) values for the SE systems while constructing our model. In other words, we assume that relating the \(\Delta D_{\text{SCF}}\) values to the \(\mu\) and \(\alpha\) properties of the monomers is adequate, because, as we have just shown, \(\Delta D_{\text{SCF}} \approx \Delta D_{\text{exact}}\) for such species. We should note that the neglect of dispersion contributions to the binding energy may be acceptable for the alkali halide cluster anions treated here, but it would not be appropriate when treating clusters of species with much lower dipole moments [e.g., \((\text{HCN})_n\) or \((\text{H}_2\text{C-CN})_n\)] for which it is known that dispersion terms are crucial fractions of the total binding energies.\(^{28}\)

Since we concluded that reproducing the \(\Delta D_{\text{SCF}}\) binding energies would be satisfactory to make relatively good estimates of the electron binding energies for our SE species, we now move on to discuss how such binding energies are obtained. One needs to recall that

\[
\Delta D_{\text{SCF}} = \Delta D_{\text{KT}} + \Delta \Delta D_{\text{SCF}}
\]

(as described in Ref. 9) and therefore, to reproduce the \(\Delta D_{\text{SCF}}\) energies one has to find a way to estimate \(\Delta D_{\text{KT}}\) and \(\Delta \Delta D_{\text{SCF}}\).

We found that the KT electron binding energies (\(\Delta D_{\text{KT}}\)) for our SE species correlate well with \(\mu / r^2\), where \(\mu\) is the dipole moment of the neutral monomer that the SE species contains (see Table I) while \(r\) is the distance between the symmetry center of the SE system (where the excess electron is expected to reside) and the alkali atom. In Table II we provide the \(\mu / r^2\) values in Fig. 2(a) and 2(b) we illustrate the correlation between \(\Delta D_{\text{KT}}\) data and \(\mu / r^2\) values for the dimers and trimers. The observed correlation arises because the electron–dipole interaction potential is given by \(\mu \cos \theta / r^2\) and the KT binding energy involves primarily the electrostatic interaction of the extra electron with the dipole potential of the neutral parent molecule. Of course, the value of \(r\) reflects the eventual balance between electron–dipole attraction and the repulsion between the dipoles. In this sense, \(r\) relates to the ionic radius of the alkali cation as we show in Fig. 3.

The \(\Delta D_{\text{KT}}\) data points obtained from the \textit{ab initio} calculations performed for the dimers fit a first-order polynomial that was found (via linear regression) to be

\[
\Delta D_{\text{KT}}(\mu / r^2) = 9.20878 \mu / r^2 - 0.03716
\]

with the regression correlation coefficient equal to 0.969 [see Fig. 2(a)]. The data points obtained from the \textit{ab initio} calculations performed for the trimers fit a first-order polynomial of the form:

\[
\Delta D_{\text{KT}}(\mu / r^2) = 11.42039 \mu / r^2 + 1.74548
\]

with the regression correlation coefficient equal to 0.979 [see Fig. 2(b)]. The fact that the linear slope shown in Fig. 2(b) is larger than that of Fig. 2(a) simply reflects the fact that there are three electron–dipole attractive potentials operative in the trimer and only two in the dimer.

The fact that the \(\Delta D_{\text{KT}}\) correlates well with the corresponding \(\mu / r^2\) values lets us approximate the \textit{ab initio} \(\Delta D_{\text{KT}}\) binding energies of the SE species by using the above-given formulas [Eqs. (5) and (6)] if we have available the monomer’s \(\mu\) value and if we can obtain an \(r\) value [e.g., by using...
the relationship between the cation’s ionic radius and the \( r \) values reflected in Figs. 3(a) and 3(b) and discussed in the following.

Next, we observed that the \( \Delta D^{\text{SCF}} \) contributions to the electron binding energies for the SE species correlate well with \( \alpha/r^4 \), where \( \alpha \) is the polarizability (specifically it is the parallel component, \( \alpha_p \)) of the neutral monomer that the SE system contains. In Table II we list the \( \alpha/r^4 \) values and in Figs. 4(a) and 4(b) we show how the \( \Delta D^{\text{SCF}} \) data correlate with the \( \alpha/r^4 \) values for the dimers and trimers. The data points obtained from the \textit{ab initio} calculations performed for the dimers fit a first-order polynomial that was found with the linear regression to be

\[
\Delta D^{\text{SCF}}(\alpha/r^4) = 0.65590 \ \alpha/r^4 + 0.02551 \tag{7}
\]

with the regression correlation coefficient equal to 0.998 [see Fig. 4(a)]. The results obtained from the \textit{ab initio} calculations performed for the trimers fit a first-order polynomial that was found to be

\[
\Delta D^{\text{SCF}}(\alpha/r^4) = 1.62912 \ \alpha/r^4 + 0.05471 \tag{8}
\]

with the regression correlation coefficient equal to 0.997 [see Fig. 4(b)].

The fact that the \( \Delta D^{\text{SCF}} \) correlates well with the corresponding \( \alpha/r^4 \) values lets us predict the \textit{ab initio} \( \Delta D^{\text{SCF}} \) binding energies using the above-given formulas if we know the monomer’s \( \alpha \) value and the \( r \) value (or, the alkali cation’s ionic radius).

We have already shown why we assume \( D^{\text{SCF}} \approx D^{\text{exact}} \) for the SE species and the above-given analysis shows that the \( D^{\text{SCF}} \) electron binding energy consists of two terms \( D^{\text{KT}} \) and \( \Delta D^{\text{SCF}} \), see Eq. (4)] that can be obtained in a very simple manner when the \( \mu/r^2 \) and \( \alpha/r^4 \) values are known [see Eqs. (5)–(8)]. Therefore, it seems natural to rewrite Eq. (4) for the dimers as

\[
D^2_{\text{model}} \approx D^{\text{SCF}} = D^{\text{KT}} + \Delta D^{\text{SCF}} \\
= 9.20878 \ \mu/r^2 - 0.03716 \\
+ 0.65590 \ \alpha/r^4 + 0.02551 \tag{9}
\]
construct our formula. That is, we extend this interpolation electron binding energies for species that were not used to the results obtained with our formulas to \textit{ab initio}!

Fig. 4. \(\Delta D_{\text{SCF}}\) contribution to the electron binding energy of the SE dimers (a) and trimers (b) as a function of \(\alpha/r^4\) (see Tables I and II, as well as Sec. III B for details). The regression correlation coefficient is 0.998 [for the dimers, see (a)] and 0.997 [for the trimers, see (b)].

\[
D_{\text{model}}^2 = D_{\text{SCF}} - \frac{0.65590}{\alpha/r^4} + 9.20878, \quad \mu = 0.01165.
\] (10)

Exactly the same procedure can be used to get the formula for the trimers [by using Eqs. (4), (6), and (8)]. This gives (for the trimers)

\[
D_{\text{model}}^3 = D_{\text{SCF}} - D_{\text{CCSD(T)}} + \Delta D_{\text{SCF}}
\]

\approx 11.42039 \mu r^2 + 1.74548 + 1.62912 \alpha r^4 + 0.05471
\] (11)

[In which \(D_{\text{model}}^3\) indicates the electron binding energy obtained for the trimers (subscript “3”) with the model proposed], or

\[
D_{\text{model}}^3 = 1.62912 \alpha r^4 + 11.42039 \mu r^2 + 1.80019.
\] (12)

Having discussed the model interpolation–extrapolation formulas, Eqs. (10) and (12), we now move on to compare the results obtained with our formulas to \textit{ab initio} calculated electron binding energies for species that were not used to construct our formula. That is, we extend this interpolation formula to the extrapolation domain, keeping in mind that the model is expected to work when applied to high-symmetry SE clusters (dimers and trimers) consisting of alkali halides but not species such as (HCN)$_n^-$ for which electrostatic and relaxation affects do not dominate the electron–molecule interaction.

### C. Testing the model

First, let us examine how the \(D_{\text{model}}\) values [i.e., calculated from Eq. (10) for the dimers and from Eq. (12) for the trimers] compare to the corresponding \textit{ab initio} \(D\) values for the twelve SE species that were used to construct the model equation. In Table V we show the deviations (in %) calculated as \(\left| D_{\text{model}} - D_{\text{exact}} \right| / D_{\text{exact}}\) [where \(D_{\text{exact}}\) corresponds to the electron binding energy calculated at either CCSD(T) or CCSD level]. Clearly, the model works reasonably well because the average error is only 4% and the largest error (obtained for the LiF anionic dimer) is 10%.

Next, let us examine how well the model works when applied to SE species that were not used to construct the model equations [Eqs. (10) and (12)]. We considered four high-symmetry solvated electron species [i.e., (KF)$_m^-$ and (KCl)$_m^-$, \(m = 2,3\)] and we both (i) calculated their MP2 equilibrium geometries and electron binding energies at the CCSD(T) level as we did for the other systems discussed in this work, and (ii) estimated their electronic stabilities by using the model embodied in Eqs. (10) and (12). The results collected in Table VI indicate that the deviations between the estimated and \textit{ab initio} calculated electron binding energies are substantial yet not very large (except in the case of KF trimer where the deviation is 34%). In particular, our VDE (i.e., \(D\)) estimate for the (KF)$_2^-$ (5% deviation from the \textit{ab initio} calculated value) is satisfactory, while those for (KCl)$_2^-$ and (KCl)$_3^-$ (deviations of 15% and 14%, respectively) are significantly worse yet still qualitatively correct (see Table VI).

It has to be stressed, however, that the model proposed utilizes the distances \((r)\) between the alkali metal atom and

IV. CONCLUDING REMARKS

We conclude that the model put forth here works reasonably well for several SE species and the average errors it produces are quite acceptable considering the approximations made in constructing it. This model approximates the Koopmans’ theorem electron binding energy in terms of the dipole moments of the monomer building blocks and a size parameter $r$ that we show can be related to the Pauling ionic radius of the cation. It approximates the $\Delta$SCF detachment energy in terms of these same quantities and the parallel component of the alkali halide monomer’s polarizability. We envision this model being used in either of two ways:

(1) to estimate the electron binding energies of new dimer or trimer cluster anions by using dipole moment and polarizability data on the monomers as well as the cation’s ionic radius, or

(2) to estimate the size (i.e., $r$ value) of a dimer or trimer cluster using measured electron detachment energies and the dipole moment and polarizability of the constituent monomers.

28 The equilibrium anionic structure for KF and KCl dimers and trimers as well as the corresponding electron binding energies were calculated with the 6-311+ +G** rather than aug-cc-pVDZ basis sets because the latter basis set is not available for potassium. In addition, the 6-311+ +G** basis was supplemented with the additional 6(sp)4d set of diffuse functions centered in the center of each system.
